2006

**Objectives:** To determine the impact of establishing walk-in centres alongside emergency departments (EDs) on attendance rates, visit duration, process, costs and outcome of care.

**Methods:** Eight hospitals with co-located EDs and walk-in centres were compared with eight matched EDs without walk-in centres. Site visits were conducted. Routine data about attendance numbers and use of resources were analysed. A random sample of records of patients attending before and after the opening of walk-in centres was also assessed. Patients who had not been admitted to hospital were sent a postal questionnaire.

**Results:** At most sites, the walk-in centres did not have a distinct identity and there were few differences in the way services were provided compared with control sites. Overall, there was no evidence of an increase in attendance at sites with walk-in centres, but considerable variability across sites was found. The proportion of patients managed within the 4 h National Health Service target improved at sites both with and without walk-in centres. There was no evidence of any difference in reconsultation rates, costs of care or patient outcomes at sites with or without walk-in centres.

**Conclusions:** Most hospitals in this study implemented the walk-in centre concept to a very limited extent. Consequently, there was no evidence of any effect on attendance rates, process, costs or outcome of care.

The National Health Service (NHS) introduced the first walk-in centres during 2000, with an initial wave of 40 centres opening in various community and hospital locations.<sup>1</sup> The aim was to improve the accessibility of NHS services by providing nurse-led information and advice for minor illnesses and injuries at times and places convenient to patients. Over the following 6 years, successive waves of walk-in centres had been established, resulting in a total of 71 centres by 2005, including those opened in 2004 alongside emergency departments (EDs).

These ED walk-in centres have several aims, reflecting the current health policy.<sup>2</sup> First, they are intended to provide people with greater choice in how they access healthcare. Rather than trying to dissuade people from attending hospital with problems that are not medical emergencies, these centres reflect a patient-centred philosophy of providing services where people choose to attend. Second, local health economies were encouraged to establish walk-in centres to relieve pressure on EDs experiencing difficulty in meeting the NHS target that patients should be seen and treated or discharged within 4 h of arrival. Third, these new centres were intended to offer a more appropriate environment than an ED for people attending hospital with less serious health problems.

However, there are several uncertainties about the potential effects of this strategy. Opening a walk-in centre may improve overall access, leading to increased patient throughput, without relieving pressure on the ED. Patients treated in a nurse-led walk-in centre may not have the same experience or achieve similar outcomes compared with those seen in an ED. Finally, establishing a walk-in centre may have an effect on NHS costs, including consequential costs if patients seen in a walk-in centre have a different pattern of subsequent consultations. The evaluation of the first wave of walk-in centres (few of which were co-located with EDs) suggested that, although they provided safe<sup>3</sup> and popular<sup>4</sup> care, the cost of consultations

was relatively high and there was no evidence of reduced demand in neighbouring services.<sup>5 6</sup>

## METHODS

We describe the effect of ED walk-in centres on consultation rates, waiting times, and the process, costs and outcomes of care. A survey of patients' experience is described in a companion paper.<sup>7</sup> This is based on an evaluation of the eight walk-in centres co-located with EDs which opened during 2004.

## Overview of design

A controlled before and after study was conducted. All eight sites with a new walk-in centre established in 2004 and co-located with an ED were compared with matched EDs with no co-located walk-in centre facilities. Sites with and without walk-in centres were individually matched according to three parameters: performance on the 4 h target, size of department (based on the number of new attendances) and the proportion of patients admitted. Using data from the third quarter of 2003/4, all EDs in England were ranked into quintiles. Sites were matched so that they fell into the same quintile for the 4 h target, and into the same or adjacent quintile for the other two parameters.

The new walk-in centres worked in a closely integrated way with their co-located EDs, so that in most instances patients were assessed and allocated to either the walk-in centre or the ED according to the nature of their problem. Therefore, it was not appropriate to compare patients seen in walk-in centres with those seen in their adjacent EDs, as there would be systematic differences between these patient groups. A more appropriate comparison was between those patients attending combined emergency/walk-in centre sites (intervention sites)

**Abbreviation:** ED, emergency department

**Figure 1** Duration of visits to intervention and control sites after the opening of walk-in centres. The vertical line indicates the NHS target of 4 h within which patients should be discharged or admitted.

versus those attending similar EDs without a co-located walk-in centre (control sites).

#### Data sources

All intervention sites were visited to collect information about the aims of the walk-in centre, staffing, policies, services provided and infrastructure. This was obtained through direct observation, interviews with managers and senior clinicians and documentary analysis. The same information was obtained from control sites via telephone interviews with local managers.

Each intervention site provided details of the number of patients consulting, admitted or discharged on a monthly basis for the period from 6 months before the opening of walk-in centre to 6 months after. Identical data were collected over the same time periods at control sites, based on the opening date at the matched site.

Each intervention site provided detailed anonymised data from patient records for 200 patients consulting before and 200 patients consulting after the opening of walk-in centre. These patients were randomly selected by the research team, using a series of computer-generated numbers matched to patient ID numbers, from those consulting in a 2-week period at least 3 months after the walk-in centre opened, and the same period 1 year earlier, before the walk-in centre opened. The same data were collected for the corresponding time periods at control sites. Data extracted from patients' records included the facility consulted (walk-in centre and/or ED), age, sex, professional staff consulted, investigations, treatments, times of arrival, consultation, admission or discharge and type of consultation, including details of onward referrals.

From the above samples of 200 people consulting each site after opening of the walk-in centre (or during the same period at control sites), all those who were not admitted to hospital were sent an anonymous postal questionnaire 4 weeks' after their consultation. This included questions about re-consultations with the same health problem since attending the hospital, and the resolution of their problem. Further details on the survey methods are provided in the companion paper.<sup>7</sup>

An economic evaluation was conducted from the viewpoint of the NHS. Set-up costs for the walk-in centres were not included because it was not possible to identify these reliably and because it is more appropriate to compare the recurrent cost of providing services. Resource use before and after the opening of each walk-in centre was identified, measured for each site separately and valued. Sites provided data about

clinical staff costs and fixed and semi-fixed costs such as administrative and clerical staff, buildings, utilities, consumables and equipment. Estimation of variable costs (investigations, treatments, medication, admissions, onward referrals and re-consultations) was based on data obtained from the anonymised patient records and the patient survey described above. Because sites with walk-in centres may make greater use of nurse practitioners, and staff costs were likely to account for most of the overall consultation cost, a "time and motion" study was conducted in four sites to obtain data about the proportion of time spent by different types of staff with different types of patients. As admissions accounted for a high proportion of the total cost per patient, but are unlikely to be related to the existence of a walk-in centre, these were excluded from the main analysis but included in a sensitivity analysis.

#### Analysis

Comparisons between intervention and control groups were conducted using appropriate (linear or logistic) regression models which took account of the clustered nature of the data and of individuals' different probabilities of being sampled across time and sites.

## RESULTS

### Site visits: implementation of walk-in centres

The latest wave of eight walk-in centres co-located with EDs had implemented the walk-in centre concept to a more limited extent than previous waves. In most sites, from the perspective of patients, the service appeared little different from the way it had been provided before. Few of the walk-in centres had a distinct visible identity and none had advertised their existence to the local population. Three of the new facilities were not known locally as walk-in centres, and in several sites the walk-in centre was effectively a re-badging of a pre-existing service.

There was resistance at several sites to the concept of providing a more convenient walk-in service, due to concerns that increasing accessibility would lead to an increase in demand. Most managers and doctors believed the main function of the walk-in centre was to reduce demand on the ED rather than to increase patient choice. At the majority of sites, patients could not directly walk into the new facility, but were directed there by a receptionist or after a nurse assessment. The staffing of the walk-in centres and their co-located EDs was flexible, with nurses and doctors moving between each facility according to demand.

N	1315	1534	785	761	1546	1530	
Mean visit duration (min)	156.6	143.9	142.2	107.6	134.8	133.5	0.44
Cases complying with 4 h target (%)	87.4	89.0	94.6	95.6	94.8	94.8	0.73

ED, emergency department; WIC, walk-in centre.

\*p Value for group×time interaction—that is, difference in change between baseline and follow-up for intervention vs control sites.

### Effect on patient throughput

Patient throughput increased during the study, at hospitals both with and without walk-in centres. The mean increase in attendances was 813 per month (95% CI –30.3 to 1655,  $p = 0.06$ ) and 270 per month (95% CI –114 to 655,  $p = 0.17$ ) in the intervention and control groups, respectively. There was no evidence of any difference in change between the intervention and control groups between the pre- and post-periods (difference in change = 542, 95% CI –347 to 1431,  $p = 0.23$ ). Although the point estimate suggested that there was a greater increase in throughput at intervention sites (ie, those with walk-in centres), there was wide variability between individual sites. The estimate itself had a very wide CI including zero, indicating that this finding might have resulted by chance.

### Effect on visit duration

The mean visit duration (time from arrival to being admitted or discharged) reduced during the study at sites with and without walk-in centres, and there was no significant difference between these types of sites. The proportion of patients managed within the target time of 4 h was 94.8% at both intervention and control sites. Table 1 provides details of these results. Figure 1 illustrates the effect of the 4 h target on waiting times.

### Process of care

There were few differences between the processes of care provided at sites with and without walk-in centres, in terms of investigations and treatments. However, patients attending a walk-in centre were more likely to be managed by a nurse, without the involvement of a doctor. Of patients seen in a walk-in centre, only 39.5% saw a doctor, compared with 95.7% of patients in EDs with a co-located walk-in centre and 86.6% of

patients in control EDs. The value of this comparison is limited because patients were, in most cases, being allocated at intervention sites to the walk-in centre because they were suitable for nurse care.

### Resource utilisation and costs

Table 2 shows the estimated total cost by the resource use group for the January–March quarter before and after the opening of the walk-in centres. The year-on-year total cost increased by 22% in the intervention group and by 10% in the control group. The differential between the two groups is largely due to the difference in the increase in clinical staff costs of 28% in the intervention group and 15% in the control group.

Table 3 shows the cost per patient. Costs increased at the intervention sites by £6.22 per patient, but costs at the control sites also increased (£8.28 per patient), so there was no evidence of any difference between the change in cost per patient at the intervention sites compared with that at the control sites (–£3.06; 95% CI –16.50 to 10.39). When admission costs are included in a sensitivity analysis, there remains no evidence of difference in the change in cost per patient (–£20.97; 95% CI –64.98 to 23.04 per patient).

### Patient outcome and reconsultation

A total of 704 patients completed and returned a questionnaire successfully, giving an overall survey response rate of 36.1%. Almost half of these respondents had a reconsultation about the same problem in the 4 weeks after they attended the hospital, and the majority of these consultations were with doctors or nurses in general practice (table 4). There was no evidence of any difference between patients seen at hospitals with or without walk-in centres; nor was there any evidence of differences in patient outcomes (table 5).

**Table 2** Estimated total cost (£000) of intervention and control sites for a 3-month period January–March in 2004 and 2005 by category of resource use

## CONCLUSIONS

In most cases, the new co-located walk-in centres seem to have implemented the original walk-in centre concept to a more limited extent than the earlier centres, although there are considerable differences between individual sites. Some walk-in centres have created a slightly different organisational environment, with a greater role for nurse management of patients compared with standard EDs, but in other cases the main change seems to be in the way that episodes of care are labelled. It is therefore unsurprising that overall there are few differences between EDs with or without co-located walk-in centres in terms of patient attendance rates, waiting times, costs or outcomes.

The intervention sites seem to have nominally achieved the aim of diverting some activity from EDs to walk-in centres, but this was mainly an exercise in streaming, with no evidence of benefit or detriment to patients or to health service costs. It is difficult to determine whether these walk-in centres have achieved the aim of helping EDs meet access targets. Visit durations improved at sites both with and without walk-in centres, and it is likely that those sites without walk-in centres used other strategies to reduce waiting times.<sup>8,9</sup> The current

data support the findings of previous research that the waiting time target has had a galvanising effect on patient management within EDs, with many patients being admitted or discharged just within the 4 h limit.<sup>10</sup>

There seems to be a disconnection between the centrally determined aims of walk-in centres alongside EDs and the way in which this policy has been implemented locally. This may reflect a perceived tension between the aims of improving access to care and at the same time reducing pressures on co-located EDs. Historically, EDs have struggled to meet increasing demand, while also being expected to reduce the waiting times. They have used various strategies to discourage people from attending with conditions that are neither accidents nor emergencies.<sup>11</sup> Encouraging people to “walk in” with any problem to suit the convenience of the individual requires a major cultural shift in attitude on the part of service providers, which has not yet been achieved.

This study has a number of limitations. First, it was conducted after the centres had been open for only a few months, and the organisational model and patients' use of the new facilities may change once the facility is well established. Second, most of the

data were collected from routine records, which may be of uncertain quality. Third, the low survey response rate limits the generalisability of the findings on patients' experience reported here. Finally, although it included all the new EDs-focused walk-in centres in England, the small number of sites provides limited power to detect quantitative differences.

Establishing walk-in centres co-located with EDs is just one of several wide ranging initiatives intended to provide people with choice as to how they access care.<sup>12</sup> This study does not address the issue of other alternatives that might be adopted to improve waiting times in EDs or to improve access to primary care. The investment used to introduce walk-in centres could equally have been utilised in existing EDs, used to expand emergency nurse practitioner roles or increase integration with primary care services outside hospital. Further research should therefore compare the different models of organisation in order to determine the optimal approach.

#### ACKNOWLEDGEMENTS

We thank patients and staff in NHS walk-in centres and EDs who participated in the various components of the evaluation. We also thank Miss Susan Sprigge, Miss Sally Ogden, Ms Ita Connolly and Dr Jonathan Bengner for their valuable help.
